ABSTRACT

We have embarked on a project, under the aegis of the Nearby Stars (NStars)/ Space Interferometry Mission Preparatory Science Program to obtain spectra, spectral types, and, where feasible, basic physical parameters for the 3600 dwarf and giant stars earlier than M0 within 40 parsecs of the sun. In this paper we report on the results of this project for the first 664 stars in the northern hemisphere. These results include precise, homogeneous spectral types, basic physical parameters (including the effective temperature, surface gravity and the overall metallicity, $[M/H]$) and measures of the chromospheric activity of our program stars. Observed and derived data presented in this paper are also available on the project's website <http://stellar.phys.appstate.edu/>.

Subject headings: astronomical databases: surveys — stars: abundances — stars: activity — stars: fundamental parameters — stars: statistics

1. Introduction

The three institutions represented by the authorship of this paper are cooperating on a project under the NASA/JPL Nearby Stars / Space Interferometry Mission Preparatory Science program to obtain spectroscopic observations of all 3600 main-sequence and giant stars with spectral types earlier than M0 within a radius of 40 pc. We are obtaining blue-violet spectra at classification resolution ($1.5 - 3.6\text{\AA}$) for all of these stars. These spectra are being used to obtain homogeneous, precise, MK spectral types. In addition, these spectra are being used in conjunction with synthetic spectra and existing intermediate-band Strömgren *wavy* and broad-band *VRI* photometry to derive the basic astrophysical parameters (the effective temperature, gravity and overall metal abundance $[M/H]$) for many of these stars. We are also using these spectra, which include the Ca II K and H lines, to obtain measures of the chromospheric activity of the program stars on the Mount Wilson system. The purpose of this project is to provide data which will permit an efficient choice of targets for both the Space Interferometry Mission (SIM) and the projected Terrestrial Planet Finder (TPF). In addition, combination of these new data with kinematical data should enable the identification and characterization of stellar subpopulations within the solar neighborhood.

Observations for this project are being carried out on the 1.9-m telescope of the David Dunlap Observatory in a northern polar cap ($\text{DEC} > +50^\circ$), the 0.8-m telescope of the Dark Sky Observatory ($-10^\circ \leq \text{DEC} \leq +50^\circ$), the 2.3-m Bok telescope of Steward Observatory ($-30^\circ \leq \text{DEC} \leq -10^\circ$) and the 1.5-m telescope at Cerro Tololo Interamerican Observatory ($\text{DEC} \leq -30^\circ$), although there is considerable overlap between all of these samples. In this paper, we report on results for the first 664 stars, all observed at the Dark Sky Observatory.

2. Observations and Calibration

The observations reported in this paper were all made on the 0.8m telescope of the Dark Sky Observatory (Appalachian State University) situated on the escarpment of the Blue Ridge Mountains in northwestern North Carolina. The Gray/Miller classification spectrograph was employed with

two gratings with $600\text{ grooves mm}^{-1}$ and $1200\text{ grooves mm}^{-1}$ and a thinned, back-illuminated 1024×1024 Tektronix CCD operating in the multipinned-phase mode. The observations were made with a $100\mu\text{m}$ slit, which corresponds to approximately $2''$ at the focus of the telescope; average seeing at the Dark Sky Observatory (DSO) is about $3''$. The $100\mu\text{m}$ slit with the two gratings yields 2-pixel resolutions of 3.6\AA and 1.8\AA and spectral ranges of $3800 - 5600\text{\AA}$ and $3800 - 4600\text{\AA}$ respectively. The lower-resolution spectra were used primarily for the late-type stars in the sample (later than G5) whereas the higher-resolution spectra were used primarily for the earlier-type stars. An iron-argon hollow-cathode comparison lamp was used for the wavelength calibration, and all the spectra were reduced with standard methods using IRAF¹.

The 1.8\AA resolution spectra were rectified using an X-windows program, `xmk19`, written by one of us (ROG) and were used in that format for both spectral classification and for the determination of the basic physical parameters. For the late-type stars rectification is problematical as no useful “continuum” points can be identified. In addition, the energy distribution contains useful information for both the spectral classification and the determination of the basic physical parameters. We have therefore made an attempt to approximately flux calibrate the 3.6\AA resolution spectra even though they were obtained with a narrow slit. During the course of our observations for this project at DSO over the past three years, we have, at intervals of a few months, made observations of spectrophotometric standards at a variety of airmasses. These standard observations have been used to approximately remove the effects of atmospheric extinction and to calibrate the spectrograph throughput as a function of wavelength. Except for observations made at high airmasses (> 1.8 airmasses) this procedure yields calibrations of *relative* fluxes with accuracies on the order of $\pm 10\%$. While this is sufficient for the purposes of accurate spectral classification, the determination of the basic physical pa-

¹IRAF is distributed by the National Optical Astronomy Observatories (NOAO). NOAO is operated by the Association of Universities for Research in Astronomy (AURA), Inc. under cooperative agreement with the National Science Foundation

rameters requires a more accurate flux calibration. This we have achieved by “photometrically correcting” the fluxes using Strömgren photometry. The DSO 3.6Å resolution spectra have a spectral range which includes three of the four Strömgren bands, *v*, *b* and *y*. We perform numerical photometry on these spectra and use the absolute flux calibration of the Strömgren system (Gray 1998) to derive flux corrections at the effective wavelengths of the three photometric bands. Interpolation and extrapolation of these corrections yield flux corrections over the entire observed spectrum. From comparison with spectrophotometric observations in the literature, we find that this procedure yields not only relative but also absolute fluxes with accuracies of about $\pm 3\%$ over nearly the entire spectral range. Fortunately, most of our program stars with spectral types of K3 and earlier have Strömgren photometry. For the later-type stars without Strömgren photometry, other considerations (see §4) preclude the derivation of basic physical parameters from our spectra and so the lack of accurate fluxes is not otherwise limiting.

All of the spectra obtained for this project are available on the project’s website². Rectified spectra from DSO have an extension of `.r18` or `.r36` depending on the resolution. The 3.6Å resolution flux spectra, which have not been photometrically corrected, are normalized at a common point (4503Å) and have an extension of `.nor`, whereas photometrically corrected spectra are available in a normalized format (`.nfx`) and in terms of absolute fluxes (`.flx`) in units of $\text{erg s}^{-1} \text{cm}^{-2} \text{Å}^{-1}$. Spectra obtained at the other observatories (see §1) are also available on this website, and will be the subject of future papers.

3. Spectral Classification

The spectral types for the stars in this paper were obtained using MK standard stars selected from the list of “Anchor Points of the MK System” (Garrison 1994), the Perkins catalog (Keenan & McNeil 1989) and, for late K and early M-type dwarfs from Henry et al. (2002). A list of the standards used (and the actual spectra) can be found on the project website.

The program stars were first classified independently on the computer screen by eye (using the graphics program `xmk19`) by at least two of the authors and then the spectral types were compared and iterated until complete agreement was obtained. There are significant overlaps between the samples observed with the four telescopes employed for this project to ensure homogeneity of our spectral types over the entire sky. This homogeneity is further ensured by a significant overlap in the MK standards used for each sample, and close scrutiny of the non-overlapping standards to verify consistency. The spectral types for the first sample of 664 stars from the northern hemisphere observed at DSO are recorded in Table 1. These spectral types are multi-dimensional, as they include not only the temperature and luminosity types, but also indices indicating abundance peculiarities and the degree of chromospheric activity.

Chromospheric activity is evident in our spectra through emission reversals in the cores of the Ca II K & H lines, and in more extreme situations, infilling and emission in the hydrogen lines. We have indicated these different levels of chromospheric activity in the spectral types with the following notation: “(k)” indicates slight emission reversals or infilling of the Ca II K & H lines are visible; “k” indicates emission reversals are clearly evident in the Ca II K & H lines, but these emission lines do not extend above the surrounding (pseudo) continuum; “ke” indicates emission in the Ca II K & H lines above the surrounding (pseudo) continuum, usually accompanied with infilling of the H β line, and “kee” indicates strong emission in Ca II K & H, H β and perhaps even H γ and H δ . Because chromospherically active stars tend also to be variable, the chromospheric activity “type” will also vary. We have, therefore, noted the observation date in the notes to Table 1 for those stars which have been designated either “ke” or “kee”. Stars of special astrophysical interest have been noted in §6 as well as in the notes to Table 1. Specific dates of observation for all of the stars observed on this project can be found in the “footers” of the spectra themselves, available on the project website.

Spectral types are important to this project because 1) they provide the first detailed look at our data and enable us to pick out peculiar and astrophysically interesting stars and 2) accurate

²<http://stellar.phys.appstate.edu/>

spectral types yield beginning values for our determination of the basic physical parameters and provide a check on the derived physical parameters. In addition, our spectral types enable us to refine the census of stars within 40pc of the sun. Figure 1 shows an HR diagram based on the spectral types in Table 1 and *Hipparcos* parallaxes (ESA 1997). Note the sharp lower edge to the main sequence and the good separation between the luminosity classes. Note, however, the handful of stars scattering below the main sequence. These stars, without exception, have large parallax errors. Most of these stars are in double and multiple systems, explaining the parallax errors. Our spectral types confirm that these stars lie significantly beyond 40pc. These stars are listed in Table 2.

4. Basic Physical Parameters

An important goal of this project is to derive the basic physical parameters - the effective temperature, the surface gravity and the overall metallicity - for as many of our program stars as possible.

4.1. Determination of the Basic Physical Parameters

To determine these parameters, we use a technique similar to that devised by Gray, Graham & Hoyt (2001) which fits the observed spectra and fluxes from medium-band (Strömgren *uvby*) and broad-band (Johnson and Johnson-Cousins *VRI*) photometry, and, when available, IUE spectra, to synthetic spectra and fluxes. The fit is achieved by minimizing a χ^2 statistic formed from the point-to-point squared differences between the synthetic and observed spectra plus a similar sum over the squared differences between the observed and synthetic fluxes. The sum of the squared differences for the spectra are given approximately three times the weight of the sum of the squared differences over the fluxes in the final χ^2 . The synthetic spectra and fluxes are based on Kurucz (1993) ATLAS9 stellar atmosphere models (calculated *without* convective overshoot) and the synthetic spectra are computed with the spectral synthesis program SPECTRUM³ (Gray & Corbally

1994). Since the publication of the Gray, Graham & Hoyt paper, much effort has been put into improving the spectral line list used by SPECTRUM including updating the oscillator strengths with the latest critically evaluated values from the NIST website⁴. Full details can be found on the SPECTRUM website.

The minimization of the χ^2 statistic is carried out by the multidimensional downhill simplex algorithm *amoeba* (Press et al. 1992). We have modified the Gray, Graham & Hoyt technique by introducing a graphical front end (*xfit16*) to this algorithm, which allows the user to find visually an approximate global solution which is then polished using the SIMPLEX engine. Any of the four basic physical parameters (T_{eff} , $\log g$, ξ_t - the microturbulent velocity - and $[M/H]$ - the overall metal abundance) may be held fixed or allowed to vary in the solution. A further improvement on the Gray et al. technique is the possibility to introduce observed fluxes not only from Strömgren *uvby* photometry, but from Johnson and Johnson-Cousins *VRI* photometry and from IUE spectra. In addition, *xfit16* can rotationally broaden the synthetic spectra, and thus is capable of treating even high $v \sin i$ stars. The graphical program *xfit16* can access multiple libraries of synthetic spectra for each of the different datasets in the project (for instance, the two dispersions from DSO, spectra from CTIO, the David Dunlap Observatory and the Bok telescope of Steward Observatory). The program *xfit16* allows the user not only to verify that the solution obtained is the global solution, but to judge visually the quality of the solution and to decide if any of the input data are defective. While *xfit16* allows the user to deredden the observed fluxes, the reddening for all of our program stars was assumed to be zero.

For the B- and early A-type stars in our program, we utilized observed fluxes from the Strömgren *u*, *b* and *y* bands and, when available, IUE spectra obtained from the MAST IUE website⁵. The flux calibration used for the Strömgren photometry is that of Gray (1998). Because the metallic lines in these stars are quite weak and thus do not have much leverage on the solution, the solution was first optimized with $[M/H]$ held

fixed at 0.00, and then $[M/H]$ was adjusted manually until good agreement was obtained visually with the metallic-line strengths. The solution was then re-optimized and $[M/H]$ readjusted if necessary. For these stars, a microturbulent velocity of 2 km s^{-1} was assumed. The IUE spectra, when available, were valuable in determining $[M/H]$ because line blanketing is much greater in the ultraviolet. An example of a SIMPLEX/`xfit16` solution for an early A-type star, HD 47105, is shown in Figure 2.

For the late A-, F- and early G-type stars IUE spectra were generally not available, and so the flux solution was constrained by fluxes from Strömgren u , b and y photometry. For these stars, all four physical parameters were allowed to vary to derive the final solution.

For the late G- and K-type dwarfs, a number of points had to be taken into consideration to achieve good solutions. First, for these cooler stars the flux solution is not well constrained by observed fluxes from the Strömgren bands, but it is necessary to include photometric fluxes from the red and the near infrared in the form of Johnson and/or Johnson-Cousins VRI photometry. We have used the absolute flux calibration for the Cousins R and I bands of Bessell (1990). To en-

sure uniformity, when only Johnson VRI photometry was available for a star, we used the equations of Fernie (1983) to transform Johnson $V - R$ and $V - I$ colors to Johnson-Cousins $V - R$ and $V - I$ colors and then used Bessell’s calibration. Unfortunately, many of our late G- and K-type stars do not have either Johnson or Johnson-Cousins VRI photometry. We have found, however, that for *dwarf* stars the following equations are able to predict Johnson-Cousins $V - R$ and $V - I$ colors from Strömgren $b - y$ colors in the range $0.4 < b - y < 0.8$ with an accuracy of 0.015 magnitude for $V - R$ and 0.03 magnitude for $V - I$.

$$V - R = 1.30(b - y) - 0.17$$

$$V - I = 2.32(b - y) - 0.25$$

We can detect only a slight dependence on metallicity in these relationships, well within the errors for stars with $[M/H] > -0.7$. By happy circumstance, most of the very metal-weak stars in our sample have VRI photometry. The Kurucz fluxes in the Strömgren u band do not reproduce well the observed fluxes in the late G- and K-type stars, and so the u band fluxes are not used in the SIMPLEX solution for these stars.

It is unfortunate that neither the energy distributions of the late G- and K-type dwarfs nor our classification spectra strongly constrain the surface gravity for these stars. In the B, A, F and even early G-type stars the Balmer jump strongly constrains the surface gravity, but this feature is too weak to serve this purpose in the late G and K-type stars. The normal MK luminosity criteria in the K-type stars (the strength of the CN band, and certain lines of ionized species such as Sr II $\lambda 4077$ and Y II $\lambda 4376$ – both used in ratio with adjacent Fe I lines) do not offer sufficient leverage in the SIMPLEX solutions to yield accurate (± 0.10 dex) values for $\log g$ in the *dwarfs*. We have found that allowing $\log g$ to be a free parameter in the SIMPLEX solution for the late G- and K-type dwarfs often results in an unreliable (usually too low) value for that parameter in the final solution. We have therefore constrained $\log g$ to the value implied by the *Hipparcos* parallax and the mass-luminosity relationship (Gorda & Svechnikov 1998). We have further constrained $\xi_t = 1.0 \text{ km s}^{-1}$. With these constraints, we generally obtain good to excellent solutions for dwarfs of spectral type K3 and earlier. An example of such a fit for a K3 dwarf can be seen in Figure 3.

Later than K3, however, the quality of the synthetic spectra and fluxes, especially in the spectral region used (3800 – 5600 Å) begins to deteriorate for the dwarf stars. It is clear that in this spectral region, for $T_{\text{eff}} < 4500 \text{ K}$, a significant contributor to the continuous opacity is missing in both ATLAS9 and SPECTRUM. Synthetic fluxes normalized and matched in the red to observed fluxes similarly normalized are too high compared to the observed fluxes in the blue-violet, and synthetic line strengths in the blue-violet are too strong. This persists even when both synthetic and observed spectra are normalized at a common point in the blue-violet. This effect is seen even in the NextGen models and synthetic spectra of Hauschildt, Allard & Baron (1999). This missing opacity in the blue-violet region is reminiscent of a similar effect found in K-giant stars in the violet by Short & Lester (1994). Short & Lester suggested this missing violet continuous opacity might be supplied by photodissociation of MgH. However, Weck et al. (2003) have recently calculated this continuous opacity; it is about an order of magnitude too small to explain the observed effect. Other

possible culprits include CaH and the O^- ion, as CaH has a dissociation energy similar to that of MgH and the ionization energy of O^- is about 2 eV. This discrepancy between observed and synthetic spectra and fluxes unfortunately prevents us from calculating basic physical parameters for dwarf stars later than K3 from our spectra.

For the late-G and K-type giants and subgiants it is likewise necessary to introduce certain constraints to derive good solutions. For most of the G and K giants and subgiants in our program, $V - K$ photometry exists, and so we have elected to use the Infrared Flux Method (IRFM) of Blackwell & Lynas-Gray (1994) to derive starting conditions and constraints for the SIMPLEX solutions. For the few giants without $V - K$ photometry, we have found that the following equations can be used to predict $V - K$ colors to sufficient accuracy (± 0.06 magnitude) for our purposes:

$$V - K = 3.80(b - y) - 0.02$$

$$V - K = 1.39(B - V)^2 - 0.98(B - V) + 1.87$$

valid for $0.55 < b - y < 0.90$ and $0.90 < B - V < 1.50$ respectively. The IRFM method uses the following polynomial to predict the effective temperature (for $V - K > 0.35$):

$$T_{\text{eff}} = 8862 - 2583(V - K) + 353.1(V - K)^2 \quad (1)$$

The luminosity of the star may be determined using the *Hipparcos* parallaxes with bolometric corrections (Flower 1996), and the radius may be determined from the Stefan-Boltzmann law. We then determine the mass for the star using the evolutionary tracks of Claret & Gimenez (1995) for $Z = 0.01$ (as many of the giants are slightly metal weak) and thence the surface gravity. The normal procedure with the giants is then to constrain the T_{eff} to the IRFM value in the SIMPLEX solution, constrain $\xi_t = 1.0 \text{ km s}^{-1}$, begin with $\log g$ as calculated above, and $[\text{M}/\text{H}]$ is manually adjusted so that the line strengths in the synthetic spectrum are approximately correct. The SIMPLEX algorithm is then allowed to polish the solution.

The basic physical parameters for this first set of program stars may be found in Table 1.

4.2. Reliability of the Basic Physical Parameters

A thorough discussion of the errors associated with the SIMPLEX method may be found in Gray, Graham & Hoyt (2001), but since a number of improvements to both the spectral synthesis program SPECTRUM and to the SIMPLEX method have been made since the publication of that paper, a review of the errors is warranted.

An excellent internal check on the precision of the SIMPLEX effective temperatures is afforded by a comparison with our spectral types. Figure 4 shows a plot of T_{eff} versus the spectral-type running number (Keenan 1984) for the dwarfs in our sample. A polynomial fit yields a scatter of $\pm 115\text{K}$, part of which is attributable to errors in the spectral types and the width of the spectral boxes. This polynomial yields the effective temperature/spectral type calibration for dwarf stars in Table 3. We conservatively estimate a random error in the SIMPLEX effective temperatures of $\pm 80\text{K}$. For an external check, we may compare the SIMPLEX effective temperatures with those derived from the IRFM method (Blackwell & Lynas-Gray 1994). To do this, we have selected those dwarfs in Table 1 which have $V - K > 0.35$ and have plotted (Figure 5) $V - K$ against the SIMPLEX effective temperatures. The solid line in that figure shows the IRFM calibration (see equation 1). As can be seen, the agreement is excellent; the scatter around the IRFM calibration is $\pm 115\text{K}$ and a close comparison suggests that the SIMPLEX temperatures are systematically only 30K hotter than the IRFM temperatures.

It is of interest to compare the SIMPLEX effective temperatures with those in the Cayrel de Strobel, Soubiran & Ralite (2001) catalog (hereinafter the [Fe/H] catalog) which contains determinations of T_{eff} , $\log g$ and [Fe/H] from the literature based on high-resolution spectroscopy. This catalog contains only data derived from digital detectors (i.e., older photographic determinations have been removed from this version of the catalog), but the data are not otherwise critically assessed. The [Fe/H] values in this catalog are derived using a number of techniques, ranging from the curve of growth method to spectral synthesis.

Figure 6 shows that for the G and K-type stars in common there is good agreement between the

SIMPLEX values of T_{eff} and those of the [Fe/H] catalog ($\sigma = 100\text{K}$, with a negligible zero-point difference), but in the F-type stars there is a systematic difference in the sense that the SIMPLEX effective temperatures are about 100K hotter than the literature values. There is, however, good agreement at G0 and for the early F-type stars.

This systematic difference in the F-type stars can be traced to a faulty convective over-shoot algorithm included in the ATLAS9 stellar atmosphere program (Kurucz 1993). This faulty algorithm introduces a systematic error in the structure of the stellar atmosphere models of the partially convective F-type star atmospheres (Smalley & Kupka 1997). This produces a distortion in the temperature scale of the F-type stars which is unfortunately reflected in many of the determinations listed in the [Fe/H] catalog.

We have recomputed the ATLAS9 models for the F-type stars with convective overshoot turned off using the implementation of ATLAS9 by Michael Lemke⁶ and used these models in the spectral libraries employed by SIMPLEX (see Gray, Graham & Hoyt (2001) for further details).

An important parameter for those who would use our data for the nearby stars in exo-planet searches is the metallicity [M/H] of the star. There is some indication that planets are found preferentially around stars with higher than solar metallicities (Gonzalez 1999).

Comparing the SIMPLEX [M/H] values with mean [Fe/H] values from the [Fe/H] catalog for the stars in common, we find small but significant zero-point differences (see Table 4). The zero-point differences for the dwarfs are generally small, but the zero-point difference for the G and K giants is quite large and requires some discussion. Many of the determinations in the [Fe/H] catalog for G and K-giants were made with stellar atmosphere models calculated with the MARCS code or its predecessors (Gustafsson et al. 1975), and this may possibly indicate a systematic difference between the Kurucz models and the MARCS models. However, we expect that this systematic difference in the giants has more to do with the fact that the abundance determinations in the [Fe/H] catalog were largely carried out at wave-

F2	6980	G2	5720

lengths $> 5000\text{\AA}$, and for the most part in the red, whereas the SIMPLEX solutions use blue-violet spectra ($3800 - 5600\text{\AA}$). We have noted above discrepancies in line strengths in the dwarfs between observed and synthetic spectra in the blue-violet for $T_{\text{eff}} < 4500\text{K}$, and we expect that we are seeing a similar phenomenon in the giants, although to a lesser degree (note that many of our giants have $T_{\text{eff}} < 4500\text{K}$). Missing continuous opacity in the blue-violet would lead to greater line strengths in the models, and thus systematically negative values for $[\text{M}/\text{H}]$.

Having applied the zero-point corrections in Table 4 to the SIMPLEX $[\text{M}/\text{H}]$ values, we find excellent agreement with the $[\text{Fe}/\text{H}]$ catalog values (see Figure 8). The $[\text{M}/\text{H}]$ values in Table 1 have had these corrections applied. The random error in the comparison is only ± 0.09 dex, hardly larger than the internal scatter in the $[\text{Fe}/\text{H}]$ catalog (≈ 0.08 dex, illustrated with error bars on one point in the figure). This is an impressive result, considering that the $[\text{Fe}/\text{H}]$ catalog values were determined from high resolution spectra. Such accurate and homogeneous $[\text{M}/\text{H}]$ values for a large sample of nearby stars will make possible a number of investigations, including examination of the hypothesis that planets are found preferentially around metal-rich stars. We will consider this hypothesis in paper II of this series.

5. Chromospheric Emission

All of the spectra obtained for this project include the Ca II K & H lines and thus can be used to

obtain measures of the chromospheric emission, as emission from the chromosphere can be detected in the cores of these very strong lines. This is an important measurement, as chromospheric emission can be an indication of the age of a star and/or its binary status. An age determination can be important for exo-planet searches, as an indication of a young age for a star might preclude observations using interferometric or coronagraphic techniques due to the complicating effects of zodiacal light from a remnant protoplanetary disk.

We measure the chromospheric emission in our program stars by calculating relative fluxes in four wavelength bands (see Figure 9), two of which are centered on the Ca II K & H lines. The other two bands measure fluxes in the “continuum” just shortwards and longwards of Ca II K & H. These bands are essentially identical to those used in the Mount Wilson chromospheric activity survey program (Baliunas et al. 1995) except that the bands centered on Ca II K & H are wider (4\AA) than those used at Mount Wilson (1\AA) because our spectra are of lower resolution. Our instrumental chromospheric emission index is calculated, like the Mount Wilson index, with the following equation:

$$S = 5 \frac{K + H}{C_1 + C_2}$$

This index is defined in such a way that it is insensitive to the local slope of the continuum in the vicinity of the Ca II K & H lines. Thus, we find that this index is identical (within a few thousandths) whether we use flux-calibrated spectra or uncalibrated raw counts. We determine this

TABLE 4
ZEROPPOINT DIFFERENCES:

Stellar Type	Resolution	Zeropoint
F & G dwarfs	1.8 Å	0.02
G & K dwarfs	3.6 Å	0.05
G & K giants	3.6 Å	0.23

index by using a feature in the spectral classification program `xmk19` that allows the user to shift the spectrum in wavelength to exactly align the *K* and *H* bands with the cores of the Ca II K & H lines and which then carries out a numerical integration over the four bands. To ensure accuracy in the numerical integration over these bands, we resample the spectrum into 0.1 Å bins.

To place this chromospheric index on the Mount Wilson scale, it is necessary to use “standard” stars to derive a transformation equation. Unfortunately, all solar-type stars show some variability in the chromospheric index, and those with higher values of *S* are generally more variable. What this means is that unless one has observations taken near in time to Mount Wilson observations, it is impossible to derive an exact transformation equation. One, however, can derive a transformation of sufficient accuracy to characterize stars as active, inactive, etc. by selecting from the Mount Wilson list (Baliunas et al. 1995) those stars that do not show long-term secular trends or irregular behavior as calibration stars. The stars we have selected for this purpose are listed in Table 5. The resulting calibration for the 1.8 Å resolution spectra is shown in Figure 10. To fit the trend in Figure 10, we have employed a cubic fit given by the following equation:

$$S_{\text{MW}} = -39.976S_{18}^3 + 43.335S_{18}^2 - 11.592S_{18} + 1.041$$

for $S_{18} < 0.361$. For $S_{18} \geq 0.361$ (the inflection point of the above cubic), the curve is extended with a straight line, having the slope of the cubic at the inflection point:

$$S_{\text{MW}} = 4.067S_{18} - 0.845$$

This straight line is also used to extrapolate to

values of S_{MW} outside the range represented by the calibration stars.

We estimate the errors in this transformation allow a determination of the Mount Wilson activity index, S_{MW} , to an accuracy of 5% with larger uncertainties (including unknown systematic errors) for $S_{\text{MW}} > 0.8$. To ensure compatibility of the derived S_{MW} values from the 3.6 Å resolution spectra with the 1.8 Å spectra, we first transform the instrumental S_{36} values onto the instrumental S_{18} system and then use the above calibration. The transformation from the S_{36} system to the S_{18} system is determined by using stars observed with both resolutions within a time frame of a few months. This transformation is linear, with a slope of unity and a zeropoint difference of 0.039. The scatter in this transformation, an indication of the precision with which we can measure S_{MW} , is ± 0.010 .

The S_{MW} index measures the flux in the core of the Ca II K & H lines, but there are both photospheric and chromospheric contributions to this flux. The photospheric flux may be removed approximately following the procedure of Noyes et al. (1984) who derive a quantity $R_{\text{HK}} \propto F_{\text{HK}}/\sigma T_{\text{eff}}^4$ where F_{HK} is the flux per cm^{-2} in the H and K bandpasses. R_{HK} can be derived from S_{MW} by modeling the variation in the continuum fluxes (in bands C_1 and C_2) as a function of effective temperature (using $B-V$ as a proxy). R_{HK} must then be further corrected by subtracting off the photospheric contribution in the cores of the H & K lines. The logarithm of the final quantity, R'_{HK} is then a useful measure of the chromospheric emission, essentially independent of the effective temperature. We have calculated R'_{HK} for all of our dwarf program stars later than F5 and earlier than

M0 with $B - V$ photometry. While the conversion of S_{MW} into R'_{HK} becomes increasingly uncertain for $B - V > 1.20$ (approximately spectral type K5), we have carried this calculation out for stars as late as K8. Both the S_{MW} and the $\log R'_{HK}$ indices are tabulated for our program stars in Table 1.

We follow Henry et al. (1996) in employing $\log R'_{HK}$ to classify stars into “Very Inactive”, “Inactive”, “Active” and “Very Active” categories (see Figure 11 and Table 1). The distribution of stars in Figure 11 is similar to that in Figure 7 of Henry et al., except that their study had a bias toward G-dwarfs and did not go to as late a spectral type as our project.

Figure 12 shows a histogram of the $\log R'_{HK}$ values for the program stars with $0.5 < B - V < 0.9$. This distribution may be compared directly with Figure 8 of Henry et al. It is clear that the distribution is bimodal, with a peak near $\log R'_{HK} = -5.0$ and another peak near -4.5 , very similar to that found by Henry et al. We have used the Levenberg-Marquardt method (Press et al. 1992) to fit a double-Gaussian model to this distribution; the result is shown in Figure 12 with the residuals from the fit illustrated in the lower panel. It is clear that this double Gaussian-model (peaks at $\log R'_{HK} = -4.996$ and -4.536 , with FWHM = 0.266 and 0.352 respectively – again very similar to the results of Henry et al.) fits the distribution within the errors, with the possible exception of one bin, at $\log R'_{HK} = -5.1$. This bin shows an excess (a 2.5σ result) of stars. An examination of Table 1 shows that out of the 36 stars in this bin, only 2 are metal-weak ($[M/H] < -0.50$) and 3 are slightly evolved (either classified as subgiants or having $\log g \leq 4.00$). The remaining stars in this bin are apparently normal, near-solar metallicity, chromospherically-inactive dwarfs. This result suggests that the excess stars in this bin and in all the bins representing very inactive stars ($\log R'_{HK} < -5.1$) may be due to dwarfs in a Maunder-minimum phase (see as well Henry et al. 1996, and Table 6 for a list of possible solar-metallicity Maunder-minimum dwarfs). However, as these excesses are only marginally significant statistically with the current sample, we will defer discussion of this point to later papers in this series.

Most of the stars in the “very active” category

in Figure 11 are well-known variables of either the BY Dra or RS CVn types. These stars are named in the notes to Table 1 (§6). Two exceptions are HIP 90035 = BD+01 3657 which shows strong emission in Ca II K & H, but which is not a known variable and BD-03 3040B which shows strong emission in Ca II and the hydrogen lines. See the notes in §6 and Figure 13.

6. Notes on Astrophysically Interesting Stars

HIP 7585 = HD 9986: Solar twin. Notice how closely the SIMPLEX basic physical parameters resemble those of the sun. This star is also chromospherically inactive, and has a classification spectrum indistinguishable from that of the sun. However, in a speckle survey of G-dwarfs (Horch et al. 2002), this star, while not resolved, was listed as a suspected non-single star.

HIP 16209 = LHS 173: This star is clearly metal-weak, but abundance-independent criteria place the spectral type of this star near to K7. At that spectral type the MgH band at $\lambda 4780$ appears of nearly normal strength. This luminosity (gravity) sensitive feature therefore suggests an unusually high gravity. Classified as a subdwarf K7 star by Gizis (1997).

HIP 53910 = HD 95418: Some sharp lines, Fe II 4233 enhanced. May be mild shell star.

BD-03 3040B: strong emission in Ca II H & K and the hydrogen lines. This star is not a known variable, but has been detected in the X-ray by ROSAT (Mason et al. 1995). Observed on Jan 31, 2001. Double with HD 96064. HD 96064 is as well chromospherically active suggesting that this is a young binary system. See Figure 13.

HIP 90035 = BD+01 3657: Very active chromospherically, but is not a known variable. Observed on Aug 8, 2000. Detected in the extreme ultraviolet (Lampton et al. 1997). A probable new BY Dra variable. See Figure 13.

7. Conclusions

We have presented a database for 664 dwarf and giant stars earlier than M0 within 40pc of the sun that includes new, homogeneous spectral types, basic physical parameters and measures of chromospheric activity. Similar data on the remain-

ing 2935 solar-type nearby stars will be presented in subsequent papers in this series. The goals of this project are to characterize the stellar population in the solar neighborhood and to provide data which will be useful in the selection of targets for the Space Interferometry Mission and the Terrestrial Planet Finder Mission. As an example of how this database could be helpful in selection of targets for discovering terrestrial planets around solar-type stars, the following table (Table 7) contains stars from the database that satisfy the following criteria:

1. Solar-type dwarfs with spectral types from F8 – G8.
2. Solar metallicity: $[M/H] > -0.10$ (following the hypothesis of Gonzalez (1999) that planets are found preferentially around metal-rich stars – the validity of this hypothesis will be tested in paper II).
3. Chromospherically inactive or very inactive: chromospheric activity can be an indicator of a young age; to find terrestrial planets with extraterrestrial life, older stars should be selected. In addition, a young age for the star might preclude observation by a spacecraft like the TPF because of the presence of excessive zodiacal light in the system.
4. Single and non-variable.

It should be noted that 13 of the stars in Table 1 already have known planets. These are

HD 19994, 46375, 75732, 89744, 137759, 143761, 145675, 186427, 190360, 210277, 217014, 217107 and 222404. These stars have not been included in Table 7.

The data presented in this paper are currently available on the project’s website and work is continuing on the remaining stars in the project which will be the subject of future papers in this series. As more results become available and the statistical significance of our results improve, we intend to examine detailed features of the distribution of chromospheric activity among solar-type stars, the validity of the hypothesis that exoplanets are found preferentially around metal-rich stars and to point out stars of astrophysical interest and of interest to the SIM and TPF missions.

This work has been carried out under contract with NASA/JPL (JPL Contract 526270) and has been partially supported by grants from the Vatican Observatory and Appalachian State University. This research made use of the SIMBAD database, operated at CDS, Strasbourg, France. We would also like to thank Jean-Claude Mermilliod for his assistance in the compilation of photometry for our database. Many thanks to graduate student Kelly Kluttz, and to undergraduate students Chris Jackolski, John Robertson, Corey Yost and Kate Hix, all at Appalachian State University, for assistance in observing.

Notes to Table1

In Table 1 there are three “note” columns pertaining to comments on the spectral types, the SIMPLEX solutions and the measurements of chromospheric activity which direct the reader to the comments on individual stars below. In some of these comments, the rotational broadening ($v \sin i$) of the star is noted; these are visual estimates used in the SIMPLEX solutions and should not be taken as actual measurements of the $v \sin i$.

HIP 518 = HD 123 = V640 Cas.

HIP 677 = HD 358: Far UV in the IUE spectra is very discrepant with respect to the model, probably due to excess metal blanketing in this chemically peculiar star. The SIMPLEX solution was carried out without IUE spectra, and is suspect.

HIP 2762 = HD 3196 = BU Cet.

HIP 3937: Chromospherically active M-dwarf, observed on Dec 1, 2000.

HIP 7585 = HD 9986: Solar twin. Notice how closely the SIMPLEX basic physical parameters resemble those of the sun. This star is also chromospherically inactive, and has a classification spectrum indistinguishable from that of the sun. However, in a speckle survey of G-dwarfs (Horch et al. 2002), this star, while not resolved, was listed as a suspected non-single star.

HIP 7762 = BD+14 253: Double with HD 10182. The *Hipparcos* parallax places this star outside the 40 pc limit.

HIP 7765 = HD 10182: Large parallax error, beyond 40pc. See Table 2.

BD+63 241: Most probably an optical, not physical double with HD 10780.

HIP 8796 = HD 11443: Rotational broadening = 50 km s⁻¹.

HIP 10064 = HD 13161: Rotational broadening = 100 km s⁻¹.

HIP 12706 = HD 16970: Rotational broadening = 150 km s⁻¹.

HIP 12828 = HD 17094: Strong metallic-line spectrum; some metals = F1.

HIP 13976 = HD 18632 = BZ Cet.

HIP 14576 = HD 19356 = Algol.

HIP 16209 = LHS 173: This star is clearly metal-weak, but abundance-independent criteria place the spectral type of this star near to K7. At that spectral type the MgH band at $\lambda 4780$ appears of nearly normal strength. This luminosity (gravity)

sensitive feature therefore suggests an unusually high gravity. Classified as a subdwarf K7 star by Gizis (1997).

HIP 17666 = HD 23439B: Ca I 4227 strong, 4500 – 4800Å region appears “veiled”.

HIP 17695: Chromospherically active M-dwarf, observed on Jan 31, 2001.

HIP 17749/50 = HD 23189A/B = GL 153A/B/C: This visual triple system has confusing nomenclature in the Simbad database. The brightest component (A) is the K2 star, the star immediately adjacent and second in brightness, which we identify as B, is an M2 star. The third and faintest of the triple, C (but which is identified in Simbad as BD+68 278A), is a K6 star.

HD 24916B: Chromospherically active M-dwarf, observed on Dec 1, 2000.

HIP 18915 = HD 25329: Metals are weak, but Ca I 4227 and the G band are almost normal for K3.

HIP 19255 = HD 25893 = V491 Per.

HIP 19335 = HD 25998 = V582 Per.

HIP 19855 = HD 26913 = V891 Tau.

HIP 19859 = HD 26923 = V774 Tau.

HIP 21482 = HD 283750 = V833 Tau: Chromospherically active K3 subgiant, observed on Dec 1, 2000.

HIP 21818 = HD 29697 = V834 Tau: Chromospherically active K4 dwarf, observed on Jan 31, 2001.

HIP 22845 = HD 31295: A3 Va kB9.5mB9.5 λ Boo; rotational broadening = 100 km s⁻¹; IUE spectra used in the SIMPLEX solution.

HIP 23875 = HD 33111: Rotational broadening = 180 km s⁻¹; IUE spectra used in the SIMPLEX solution.

HIP 23941 = HD 33256: Spectral type may also be written F5.5 V Fe-0.7.

HIP 25278 = HD 35296 = V1119 Tau.

HIP 26335 = HD 245409: Chromospherically active M-dwarf, observed on Oct 28, 2000.

HIP 27913 = HD 39587 = χ^1 Ori: G-band slightly weak & chromospherically active.

HIP 28360 = HD 40183: A1 IV-Vp kA1mA1.5 (Sr). Mild Ap star; rotational broadening = 100 km s⁻¹.

HIP 28954 = HD 41593 = V1386 Ori.

HIP 29525 = HD 42807 = V1357 Ori.

HIP 30362 = HD 256294: B8 IV kB9 Helium-weak.

NOTE.—The column headings have the following meanings: HIP stands for the designation in the Hipparcos catalog ESA (1997); HD/BD for the HD or the BD designation; SpT for the spectral type – note that some long spectral types are continued in the notes; N1: an asterisk in this column refers to a note on the spectral type; T_{eff} , $\log g$, ξ_t , $[M/H]$ refer to the basic physical parameters – the effective temperature (Kelvin), the logarithm of the surface gravity, the microturbulent velocity in km s^{-1} and the overall metal abundance on a logarithmic scale, where $[M/H] = 0.00$ refers to solar metallicity (note that if any of these quantities are enclosed in parentheses it was held fixed in the SIMPLEX solution); N2: an asterisk in this column refers to a note on the SIMPLEX solution, a “K” in this column indicates that the method used to determine the basic physical parameters was that adopted for the G & K giants; S_{MW} is the chromospheric activity index on the Mount Wilson system; $\log(R')$ is $\log R'_{\text{HK}}$, a measure of the chromospheric flux in the Ca II K & H lines; AC stands for the chromospheric activity class: VI = Very Inactive, I = Inactive, A = Active, VA = Very Active; N3 indicates the resolution of the spectrum in Ångströms used for the measurement of S_{MW} and $\log R'_{\text{HK}}$. An asterisk in this column refers to a note on chromospheric activity.

HIP 30419 = HD 44769: Rotational broadening = 100 km s^{-1} .

HIP 30630 = HD 45088 = OU Gem.

HIP 30756 = HD 257498: Large parallax error, beyond 40pc. See Table 2.

HIP 30757 = HD 45352: Double with HIP 30756 = HD 257498. This star has a parallax of 5.67 ± 2.22 , and thus, like its companion, is beyond 40pc.

HIP 31681 = HD 47105: IUE spectra used in the SIMPLEX solution. See Figure 2.

HIP 32349 = HD 48915 = Sirius: Only an SWP IUE spectrum was used in the SIMPLEX solution as the LWP and LWR spectra were all defective or had large gaps. The SIMPLEX fit is excellent, except for the K-line which is too strong in the model. This is consistent with the Am nature of Sirius.

HD 48682B = BD+43 1596. Probable optical double.

HIP 35550 = HD 56986: Rotational broadening = 100 km s^{-1} . Spectral type may also be written F2 V Fe-0.5.

HIP 35643 = HD 56963: Spectral type may also be written F2 V Fe-0.5.

HIP 38541 = HD 64090: K0: V Fe-3 CH-1.5.

HIP 40375 = HD 68834: Noisy near Ca II K & H,

so chromospheric activity measures uncertain.

HIP 41307 = HD 71155: Rotational broadening = 150 km s^{-1} .

HIP 44127 = HD 76644: Rotational broadening = 100 km s^{-1} ; IUE spectra used in the SIMPLEX solution.

HIP 45075 = HD 78362: Anomalous luminosity effect.

HIP 45963 = HD 80715 = BF Lyn. Chromospherically active K2.5 dwarf, observed on Dec 6, 2000.

HIP 46843 = HD 82443 = DX Leo.

HIP 46977 = HD 82210 = DK UMa.

HIP 47080 = HD 82885 = SV LMi.

HIP 49018 = HD 86590 = DH Leo: SIMPLEX solution poorly converged.

HIP 49593 = HD 87696: Rotational broadening = 120 km s^{-1} ; IUE spectra used in the SIMPLEX solution.

HIP 49669 = HD 87901: Rotational broadening = 250 km s^{-1} ; IUE spectra used in the SIMPLEX solution.

HIP 51502 = HD 90089: Spectral type may also be written F4 V Fe-0.5.

HIP 53910 = HD 95418: Some sharp lines, Fe II 4233 enhanced. May be mild shell star. IUE spectra used in the SIMPLEX solution.

BD-03 3040B: strong emission in Ca II H & K and the hydrogen lines. This star is not a known variable, but has been detected in the X-ray by ROSAT (Mason et al. 1995). Observed on Jan 31, 2001. Double with HD 96064. HD 96064 is as well chromospherically active suggesting that this is a young binary system. See Figure 13.

HIP 54872 = HD 97603: Rotational broadening = 150 km s^{-1} ; IUE spectra used in the SIMPLEX solution.

HIP 56035 = HD 99747: Spectral type may also be written F5 V Fe-1.0.

HIP 57632 = HD 102647: Rotational broadening = 120 km s^{-1} ; IUE spectra used in the SIMPLEX solution.

HIP 58001 = HD 103287: Rotational broadening = 150 km s^{-1} ; only SWP IUE spectrum available for the SIMPLEX fit.

HIP 59504 = HD 106112: Anomalous luminosity effect.

HIP 59744 = HD 106591: Rotational broadening = 180 km s^{-1} ; IUE spectra used in the SIMPLEX solution.

HIP 61941 = HD110379/80: γ Vir AB.

HIP 61960 = HD 110411: A3 Va kB9.5mA0 λ Boo; rotational broadening = 150 km s^{-1} ; IUE spectra used in the SIMPLEX solution.

HIP 62956 = HD 112185: Good fit except K-line in the model is stronger than in the star, consistent with the spectral type.

HIP 63076 = HD 112429: Rotational broadening = 100 km s^{-1} . Spectral type may also be written F1 V(n) Fe-0.8.

HIP 63503 = HD 113139: Rotational broadening = 100 km s^{-1} .

HIP 65477 = HD 116842: Rotational broadening = 180 km s^{-1} ; IUE spectra used in the SIMPLEX solution.

HIP 66249 = HD 118098: Rotational broadening = 180 km s^{-1} .

HIP 66252 = HD 118100 = EQ Vir: emission in Ca II K & H, $H\beta$ and $H\gamma$ filled in, SED unusual, violet end depressed. Observed May 11, 2001.

HIP 67301 = HD 120315: Rotational broadening = 120 km s^{-1} .

HIP 69400 = HD 124752: Binary with BD+68 771B.

HIP 69673 = HD 124897: K0 III CH-1 CN-0.5.

HIP 69732 = HD 125162: A3 Va kB9mB9 λ Boo; rotational broadening = 100 km s^{-1} ; IUE spectra

used in the SIMPLEX solution.

HIP 71631 = HD 129333 = EK Dra: G5 V Fe-0.7 CH-1 (k); this star is a young solar analog - it is chromospherically very active, and is a single, rapidly rotating G-type star with spot-induced variations (see Dorren & Guinan (1994) and references therein). The rapid rotation, which is just barely detectable with our 3.6\AA resolution spectra, may be responsible for the metal-weak classification. Note, however, that the SIMPLEX solution gives a nearly solar metallicity.

HIP 72848 = HD 131511 = DE Boo.

HIP 74434 = BD+19 2939B: Double with HD 135101.

HIP 75695 = HD 137909: The LWP IUE spectrum shows very broad, strong absorption due to metal blanketing. The fit was carried out without the IUE spectrum, and thus is suspect.

HIP 76051 = BD+10 2868C: Double with HD 138455; $\pi = 44.59 \pm 20.41\text{mas}$, whereas the parallax of HD 138455 is $\pi = 15.61 \pm 3.71\text{mas}$ (ESA 1997).

HIP 76267 = HD 139006: Rotational broadening = 150 km s^{-1} ; the LWP IUE spectrum inconsistent with the two SWP spectra, and was not used in the fit.

HIP 77760 = HD 142373: G0 V Fe-0.8 CH-0.5.

HIP 79492 = HD 145958 & BD+13 3091B: Both components of this visual binary system yielded precisely the same instrumental value of the chromospheric activity index S_{36} . The two components as well are nearly identical, translating into the same value for $\log R'_{\text{HK}}$.

HIP 79607 = HD 146361 = TZ CrB: An RS CVn variable. Many of the lines are veiled, probably by continuum emission; $H\gamma$ filled in with emission. Double with HD 146362.

HIP 79607 = HD 146362: Double with HD 146361. BD+07 3125B: Double with HD 146413.

HIP 80008 = HD 147365: Rotational broadening = 70 km s^{-1} .

HIP 80644 = HD 148467: Noisy spectrum.

HIP 81300 = HD 149661 = V2133 Oph.

HIP 82588 = HD 152391 = V2292 Oph.

HIP 83601 = HD 154417 = V2213 Oph.

HIP 84379 = HD 156164: Rotational broadening = 250 km s^{-1} .

HIP 87108 = HD 161868: Rotational broadening = 200 km s^{-1} ; IUE spectra used in the SIMPLEX solution.

HIP 88601 = HD 165341 = 70 Oph = V2391 Oph: Visual binary. Spectral type and the SIMPLEX so-

lution are for the primary.

HIP 90035 = BD+01 3657: Very active chromospherically, but is not a known variable. Observed on Aug 8, 2000. Detected in the extreme ultraviolet (Lampton et al. 1997). A probable new BY Dra variable. See Figure 13.

HIP 91009 = HD 234677 = BY Dra: Strong emission in Ca II H & K, H β and H γ both filled in with emission. Observed on Aug 31, 1999.

HIP 91262 = HD 172167 = α Lyr = Vega: IUE spectra used in the SIMPLEX solution.

HIP 93747 = HD 177724: Rotational broadening = 300 km s⁻¹; IUE spectra used in the SIMPLEX solution.

HIP 93805 = HD 177756: Metals and helium slightly weak; rotational broadening = 150 km s⁻¹; He I lines strong in the model compared to the star, consistent with spectral type.

HIP 95575 = HD 183255: Slightly peculiar.

HIP 97649 = HD 187642: Rotational broadening = 200 km s⁻¹; IUE spectra used in the SIMPLEX solution.

HD 335248: Optical double with HIP 102851 = HD 198550. No parallax; from its spectral type and magnitude, it is likely beyond 40pc.

HIP 104659 = HD 201891: G5 V Fe-2.5 CH-1.5.

HIP 105199 = HD 203280: Rotational broadening = 200 km s⁻¹; IUE spectra used in the SIMPLEX solution.

HIP 106231 = BD+22 4409 = LO Peg: Observed on Aug 19, 2000.

HIP 106897 = HD 206043: Rotational broadening = 120 km s⁻¹.

HIP 107350 = HD 206860 = HN Peg: flare star.

HIP 108706 = V374 Peg: A chromospherically active M-dwarf, observed Aug 23, 2000.

HIP 112870 = HD 216259: Note to spectral type: may be slightly metal-weak.

HIP 113829 = HD 217813 = MT Peg: G1 V CH-0.4 (k).

HIP 114189 = HD 218396: F0+ V kA5mA5 (λ Boo); see Gray & Kaye (2001).

HIP 114379 = HD 218738 = KZ And.

HIP 115147 = HD 220140 = V368 Cep.

HIP 116584 = HD 222107 = λ And.

HIP 116928 = HD 222603: IUE spectra used in the SIMPLEX solution.

Fig. 1.— An observational HR diagram formed from the spectral types of the 664 stars reported in this paper. The absolute magnitudes, M_V , are calculated using *Hipparcos* (ESA 1997) parallaxes. The stars scattering below the main sequence in this figure all have large parallax errors and are listed in Table 2. These stars are all evidently more distant than 40pc.

Fig. 2.— The SIMPLEX solution for the early A-type star HD 47105. The top panel shows the fit with respect to photometric fluxes (Strömgren *uvby*) and ultraviolet fluxes from IUE spectra. The bottom panel shows the fit with the observed spectrum; the difference between the observed and synthetic spectrum is seen at the bottom of the panel.

Fig. 3.— An example of a SIMPLEX fit for a K3 dwarf, HD 144872. The difference spectrum (synthetic minus observed) is shown at the bottom of the second panel; the parallel lines indicate errors of $\pm 5\%$ in the flux. The top panel shows the fit to the observed photometric fluxes; the illustrated points are, from left to right, Strömgren *u*, *v*, *b* and *y* fluxes and Johnson-Cousins *R* and *I* fluxes. The Strömgren *u* flux is not used in the solution.

Fig. 4.— The correlation between the SIMPLEX effective temperatures and the spectral type for the dwarf stars in the present sample. The scatter in this relationship is $\pm 115\text{K}$ and sets an upper limit on the random error in the SIMPLEX effective temperatures.

Fig. 5.— Comparison of SIMPLEX effective temperatures with the IRFM calibration. This comparison constitutes an external check on the SIMPLEX effective temperatures. The solid line is the IRFM polynomial (equation 1). The scatter of SIMPLEX temperatures around this curve is 115K , and the systematic difference over this range of effective temperature does not appear to exceed 30K . The IRFM temperatures are essentially independent of theoretical models.

Fig. 6.— A comparison of the SIMPLEX effective temperatures with those in the Cayrel de Strobel, Soubiran & Ralite (2001) $[\text{Fe}/\text{H}]$ catalog. The systematic difference in the F-type stars is probably due to a defective convective overshoot algorithm used in the published ATLAS9 models (Kurucz 1993). This has been corrected in the models used in the SIMPLEX solutions.

Fig. 7.— An astrophysical HR diagram based on SIMPLEX physical parameters.

Fig. 8.— A comparison between the SIMPLEX $[M/H]$ (overall metal abundance) and mean $[Fe/H]$ values from the Cayrel de Strobel, Soubiran & Ralite (2001) $[Fe/H]$ catalog. The scatter in the comparison is 0.09 dex, similar to the scatter for single stars in the $[Fe/H]$ catalog, ≈ 0.08 dex.

Fig. 9.— Numerical passbands utilized in the calculation of the chromospheric activity index S . Two bands, each 4\AA wide, are centered on the Ca II K & H lines. The C_1 and C_2 bands measure the flux in the continuum in 20\AA -wide segments of the spectrum on either side of the K & H lines.

Fig. 10.— The calibration between the instrumental S_{18} chromospheric activity index and the Mount Wilson S index. The “error bars” represent the range of variation shown by the star in Baliunas et al. (1995). The solid line shows the adopted calibration.

Fig. 11.— A plot of the chromospheric flux parameter $\log R'_{\text{HK}}$ versus the $B - V$ color. This diagram allows the classification of stars into the chromospheric activity categories “Very Inactive”, “Inactive”, “Active” and “Very Active”. All but one of the “Very Active” stars are well-known flare, BY Dra or RS CVn variables. The exception is HIP 90035 (see text and figure 13).

Fig. 12.— The distribution of the chromospheric flux parameter $\log R'_{\text{HK}}$ for stars with $0.50 < B - V < 0.90$. The distribution is clearly bimodal, with the main peak representing chromospherically inactive stars, and the secondary peak chromospherically active stars. The double Gaussian curve is a fit to the distribution. The lower panel shows the residuals associated with this fit. With the exception of the bin centered at $\log R'_{\text{HK}} = -5.1$, the fit is within the errors. The excess number of stars at $\log R'_{\text{HK}} = -5.1$ is discussed in §5.

Fig. 13.— HIP 90035 = BD+01 3657 is a chromospherically very active star which has not been classified as a flare, BY Dra or RS CVn star. Note the strong emission (in comparison with the K5 V standard 61 Cyg A) in Ca II K & H lines, and the infilling of the $H\beta$ line with emission. Likewise, BD -03 3040B is a chromospherically active early-M dwarf, not yet classified in the literature as an emission-line star, showing strong emission in Ca II K & H as well as $H\beta$, $H\gamma$ and $H\delta$.
